KEYWORDS
Sjögren’s syndrome; oral rehabilitation; dental implant; failure; marginal bone loss
ABSTRACT

The purpose of the present study was to assess the clinical outcome of dental implants in a series of patients with Sjögren’s syndrome (SS), as well as review of the literature. The study consisted of two parts: report of a case series and a systematic review. Results of the clinical series: 19 patients received 107 implants, followed for a mean of 125 months. Two patients lost 3 implants (failure rate 2.80%, 3/107). At the last follow-up, there was a mean±SD marginal bone loss (MBL) of -2.190±1.384 mm. Estimation of 4.39 mm of MBL after 30 years. Results of the review: 19 studies, including the present clinical series, with 712 implants in 186 patients (failure rate 4.11%, 29/705; failed at a mean time of 12.9±31.7 months), followed up for a mean of 72.5 months. The probability of failure was 2.8% (95% CI 1.6%, 4.1%). Primary SS had lower implant failure rate (2.54%, 3/118) than secondary SS patients (6.52%, 12/184). As a conclusion, dental implants should be considered by dentists as a viable treatment option in patients with SS, as the failure rate is fairly low. The SS patients may, however, present a higher MBL around implants than in the general population.

Sjögren’s syndrome; oral rehabilitation; dental implant; failure; marginal bone loss
INTRODUCTION

Primary and secondary Sjogren’s syndromes (SS) are systemic disorders characterized by lymphocyte infiltration and progressive destruction of exocrine glands leading to mucosal dryness, particularly of the eyes and mouth. SS have a significant impact to the oral health, and its oral implications include xerostomia due to reduced salivary flow; rampant caries; chronically inflamed and irritated oral mucosa; inflamed, enlarged, and hardening salivary glands; an increased incidence of chronic candidiasis; angular cheilitis; increased plaque retention, changes in taste perception; difficulty swallowing; chronic tissue discomfort, recurrent denture sores, difficulty masticating, and mandibular denture instability. Because of the great susceptibility for caries, patients with SS often loose many teeth during their lives and at an earlier age compared to the general population. Due to the difficulties or the inability to wear dentures because of the dry and sensitive oral mucosa, many SS patients and dentists have opted for an oral rehabilitation with dental implants instead.

There is a great demand for dental implants in SS patients, but much is conjectured on how successful this treatment may be in these patients. According to the notes of SS patients from one study, a considerable number of dentists and rheumatologists advised them not to have dental implants, as the professionals were concerned about initial osseointegration or a higher risk of implant failure. The present study aimed to assess the clinical outcome of dental implants in a series of patients with SS, as well as to review the cases of SS patients receiving dental implants described in the literature.
MATERIALS AND METHODS

The present study consists of two parts: (a) report of a case series and (b) a systematic review.

a) Case series

Materials. This retrospective study included patients treated with dental implants during the period 1980-2014 at one specialist clinic (Clinic for Prosthodontics, Centre of Dental Specialist Care, Malmö, Sweden). The study was approved by the regional Ethical Committee, Lund, Sweden (Dnr 2014/598; Dnr 2015/72).

Definitions. An implant was considered a failure if presenting signs and symptoms that led to implant removal, i.e. a lost implant.

Inclusion and exclusion criteria. Implants installed in patients being diagnosed with SS were included. The patients could have had primary (another underlying rheumatic disorder does not occur) or secondary SS (associated with another underlying rheumatic disease, such as systemic lupus erythematosus, rheumatoid arthritis, or systemic sclerosis), and the syndrome needed to have been diagnosed having performed tests to do so, usually a combination of some of (but not limited to) the following tests: blood test for the autoantibody SSA, ANA (Anti-Nuclear Antibody) test, lip biopsy (salivary gland biopsy), Schirmer tear test, examination of the surface of the eye with rose bengal and lissamine green, sialogram, salivary flow, and salivary scintigraphy.

Modern threaded cylindrical- or conical-design implants were included, and zygomatic implants were excluded. Only implants with first radiographs taken within 12 months after implant installation were considered for MBL evaluation. Negative values of MBL were considered as bone loss.
Data collection. The data were directly entered into a SPSS file (SPSS software, version 25, SPSS Inc., Chicago, IL, USA) as the dental records of the patients were being read, and it consisted of several implant-, site-, and patient-related factors.

The patients were periodically followed up by a dental hygienist at the clinic, with attendance based on individual needs.

Marginal bone level evaluation. Reproducible intra-oral radiographs were used. When there were no available digital radiographies from the baseline appointment, the analogue periapical radiographies were scanned at 1200 dpi (Epson Perfection V800 Photo Color Scanner; Nagano, Japan). Marginal bone level (MBL) was measured after calibration based on the inter-thread (pitch) distance of each implant type, the Nobel implant being the most common (0.60 mm). Measurements were taken from the implant-abutment junction to the marginal bone level, at both mesial and distal sides of each implant, and then the mean value of these two measurements was considered. MBL was calculated by comparing bone-to-implant contact levels to the radiographic baseline examination. The Image J software (National Institute of Health, Bethesda, USA) was used for all measurements.

b) Systematic review

The PRISMA Statement guidelines \(^7\) were followed.

Objective. The focused question was elaborated by using the PICO format (participants, interventions, comparisons and outcomes): What are the clinical outcomes, i.e. implant survival and MBL, of dental implants installed in patients with SS?

Search strategies. A search without time restrictions was undertaken in July 2018 in the five electronic databases: PubMed/Medline, Web of Science, Science Direct, J-Stage, and Lilacs. The following terms were used:

(Sjögren’s syndrome OR Sjögren syndrome) AND (dental implant OR oral implant)
Google Scholar was also checked. A manual search of dental implants-related journals was performed.

**Inclusion and Exclusion Criteria.** Publications reporting cases of patients diagnosed with Sjögren’s syndrome rehabilitated with implant-retained and/or implant-supported oral prosthetic rehabilitation were included. Publications reporting clinical cases of prosthetic rehabilitation not using dental implants were not included.

**Study selection.** The titles and abstracts of all reports identified through the electronic searches were read independently by the authors. For studies appearing to meet the inclusion criteria, or for which there were insufficient data in the title and abstract to make a clear decision, the full report was obtained. Disagreements were resolved by discussion between the authors.

**Data extraction.** The following data were extracted on a standard form: year of publication, number of patients, patient’s sex, age, implant type, implants placed and lost in maxilla and mandible, implant healing period, period between implant placement and loss, type of prosthetic reconstruction, MBL, and follow-up period. Contact with authors for possible missing data was performed.

c) **Statistical analyses**

The mean, standard deviation (SD), and percentage were calculated for several variables. The test performed were the following: Kolmogorov–Smirnov (to evaluate the normal distribution), Levene’s test (to evaluate homoscedasticity), Student’s t-test or Mann-Whitney (for two independent groups, continuous variables), Pearson’s chi-squared or Fisher’s exact test (for categorical variables), correlation and linear regression (to check the relationship between MBL and time of follow-up), and untransformed proportion random-effects DerSimonian-Laird method\(^8\) (for implant failure). The degree of statistical significance was considered \( p < 0.05 \). All data were statistically analyzed using the SPSS version 25 software (SPSS Inc., Chicago, IL, USA) and the software OpenMeta[Analyst].\(^9\)
RESULTS

a) Case series

A number of 19 subjects among the 2,670 patients treated with implants in this clinic were diagnosed with SS. These patients received a total of 107 oral implants – 56 implants in maxillae, 51 in mandibles, 11 in 1 male, 96 in 18 females. The mean±SD patients’ age was 63.3±8.1 (min-max, 50.4-80.3). A total of 107 threaded implants with a cylindrical design were installed - 43 Nobel turned, 38 Nobel MK III TiUnite, 13 Astra TiOblast, 10 Astra Osseospeed, 2 Bego Semados, and 1 Nobel Active. All implants were inserted with open flapped surgery in healed sites with delayed loading. The abutment connection was performed after a mean±SD healing time of 163±46 days (min-max, 74-233). The mean length of the implants was 12.8±1.8 mm (min-max, 7-15) and the mean diameter 3.74±0.17 mm (min-max, 3.3-4.3).

According to the Lekholm and Zarb classification, and concerning bone quantity, 50 implants were placed in type B, 41 in type C, and 8 in type D bone. Concerning bone quality, 9 implants were placed in type 1, 35 in type 2, 49 in type 3, and 6 in type 4. This information was available for 99 implants.

Three implants were used for single-crown restorations, 22 implants for 8 fixed partial prostheses of 2-6 prosthetic elements, 6 implants for a fixed partial prosthesis of 7-10 prosthetic elements, 74 implants for 14 full-arch fixed prostheses, and 2 implants to support an overdenture.

The patients were followed-up for a mean±SD of 125.5±82.5 months (min-max, 5.6-341.2). Two patients lost 3 implants, all due to loss/lack of osseointegration, and no implant fracture was identified. Failures were recorded for 3 Nobel turned implants only in mandible, and they happened 36 days, 8.5 months, and 159.6 months after implant installation. One of the lost implants was part of a full-arch prosthesis, and 2 implants were lost before the abutment connection and were planned for a fixed partial prosthesis of 7-10 prosthetic elements. These two lost implants were later replaced by another two implants. The three lost implants were installed in bone B2 (n=1) and C4 (n=2).
Marginal bone level evaluation. A total of 35 implants were excluded from the analysis of MBL for the following reasons: no radiograms were found in the dental records (n=13), the first radiogram was taken after one year of implant installation surgery (n=15), very short follow-up (n=5), and early implant failure (n=2). Of the remaining 72 implants, 293 MBL measurements were performed, considering the several radiological follow-ups for each implant - a mean of 4.1 MBL measurements per implant. The baseline radiograms were taken at a mean±SD of 4.4±3.2 months (min-max, 0-9.6) after implant placement. The implants were radiologically followed up for mean±SD of 125.2±80.5 months (min-max, 0.5-329.9). At the last follow-up, there was a mean±SD MBL of -2.190±1.384 mm (min, max; -7.571, 0.000) for all implants (n=72). Table 1 shows that, at the last radiological follow-up, 25% of the implants presented 3 or more millimeters of MBL. There was a steady increase in the mean MBL with time of follow-up (Table 2). There was an estimated trend to loss bone with time (Figure 1), reaching an estimated 4.39 mm of bone loss 30 years after implant installation. According to the linear regression equation (y = -0.79 – 0.01x), there was an estimated loss of 0.01 mm of bone for every additional month of follow-up. There was a moderate correlation between MBL and follow-up time (R = 0.563, R^2 = 0.317, p < 0.001, Pearson correlation). In the last radiological follow-up, the mean±SD MBL in primary SS patients (-2.371±1.451; n=53; mean follow-up 133.6±92.3 months) was higher than in secondary SS patients (-1.686±1.053; n=19; mean follow-up 101.8±13.0 months), even though with no statistically significance (p = 0.093, Mann-Whitney test).

b) Systematic review

Literature search

The study selection process is summarized in Figure 2. At the end of the process, the full-text reports of the remaining 20 articles led to the exclusion of 2 publications. In one of them the clinical case was later reported in another publication, but with follow-up information. In the second excluded article, the same cases were reported in another published study by the same research
Thus, a total of 18 publications were included in the review. As the patients of the present case series were also included in the analyses, 19 studies were included in the review.

**Description of the Studies and Analyses**

Table 3 shows detailed data of the included studies. Eighteen publications\(^4\)\(^-\)\(^6\), \(^12\)\(^-\)\(^26\) were included in the present review, and the 19 patients of the present case series were also included in the analyses. These 19 studies totaled the placement of 712 implants (45 in men, 644 in women, 23 not available) in 186 patients (8 men, 167 women, 11 not available). It was possible to distinguish some patients presenting primary SS (21 patients, 118 implants) and secondary SS (31 patients, 191 implants). At the placement of the implants the mean age of the patients was 62.5±9.3 years (min-max, 38-85; 630 implants, 166 patients). Most implants were placed in the seventh decade of life (Figure 3).

Information on follow-up was provided for 705 implants (mean 72.5±59.2 months, min-max 5-341.2), of which 29 failed (4.1%). The failure rate was higher for implants installed in the maxilla (4.82%; 11/228) in comparison to implants placed in the mandible (3.49%; 13/373), but the difference was not statistically significant (\(p = 0.416\); Pearson chi-squared test). Patients presenting primary SS had lower implant failure rate (2.54%, 3/118) than patients presenting secondary SS (6.52%, 12/184), but the difference was not statistically significant (\(p = 0.120\); Pearson chi-squared test).

Implants failed at a mean time of 12.9±31.7 months (min-max, 1-160; n=24) after implant placement. Considering the implants with information on the precise time of failure, 79.2% (19/24) occurred within 6 months after installation surgery or at the abutment connection. One implant failed at 9 months, two at 16 months, and one implant each on 24 and 160 months after installation. There was no information on time of failure for the 5 failed implants of the study of Albrecht et al. (2016).
The probability of failure (Figure 4) was 2.8% (95% CI 1.6%, 4.1%, standard error = 0.006, \( p < 0.001 \); heterogeneity: \( \tau^2 = 0.000 \), \( \text{Chi}^2 = 16.106 \), \( p = 0.446 \), \( I^2 = 0.66\% \)) for the observed mean follow-up of these studies altogether. Only the clinical cases for which the follow-up was informed were included in this analysis.
DISCUSSION

The present study aimed to assess the clinical outcome of dental implants in a series of patients with SS, as well as to review the cases of SS patients receiving dental implants described in the literature. In relation to previous reviews on the subject,\textsuperscript{27, 28} the present study performed a more careful systematic search of the literature, thus resulting in greater number of included studies. Systematic reviews are insufficiently informative if they do not include all available current evidence. This failure to rigorously synthesize the totality of relevant evidence may have a detrimental effect on treatment decisions and future research planning.\textsuperscript{29} Moreover, the present study performed a more in-depth and detailed statistical analysis of the compilation of included studies in comparison to these previous reviews.

After reviewing 712 implants placed in 186 SS patients, it was observed that the failure rate is fairly low in this population: 4.1\% over a mean of 72.5±59.2 months of follow-up. Moreover, in the majority of cases in which an implant failed to integrate, the cause is unknown. Most of the implant failures occurred within 6 months after implant installation, in agreement with other studies in which most of the lost implants fail within a couple of months after placement surgery.\textsuperscript{30, 31} In general, SS patients reported a significant improvement in the quality of life after oral rehabilitation with dental implants, with regard to satisfaction, chewing, self-assurance and self-appearance.\textsuperscript{6, 16, 20} It is, however, important to stress that oral functioning is impaired in patients with SS and continues to be impaired in patients with implant-retained prosthetics.\textsuperscript{5}

Only few studies reported data on MBL\textsuperscript{5, 15, 19, 20, 22, 25} and still most of the publications provided only vague information such as “good marginal bone levels”,\textsuperscript{22} “there was no peri-implant bone loss”,\textsuperscript{25} “no bone loss”,\textsuperscript{19} “stable bone levels”.\textsuperscript{15} Only two previous studies provided figures,\textsuperscript{5, 20} as well as the present one. The results of these two publications\textsuperscript{5, 20} suggested that MBL is not a major problem in SS patients. The present study, however, observed a very fast initial MBL in comparison to the general population followed up for at least 20 years in another study.\textsuperscript{31} This loss showed to be considerable in short- and medium-term observations, with many implants showing
MBL of 2 mm during the first years after installation and other many presenting MBL around 4 mm within the first 10 years of follow-up. Korfage et al.\textsuperscript{5} had already noticed that there probably is an increased risk of peri-implant infections in SS patients in the long term. The salivary secretion and the related self-clearance of the oral cavity is reduced in SS patients, which results in debris being collected more quickly and remaining on the implant surfaces in SS subjects than in patients with no xerostomia \textsuperscript{5}. In the study of Korfage et al.,\textsuperscript{5} SS subjects presented more gingival swelling, bleeding and increased pocket probing depths than in the controls with no salivary problems. As a consequence, the marginal periimplant tissue is more prone to continuous inflammatory insults than the peri-implant tissue in healthy patients. The reported more frequent presence of peri-implant mucositis in SS patients may be associated with an increased prevalence of peri-implantitis later on.\textsuperscript{5}

Smoking could have been a factor to influence implant failure,\textsuperscript{32} and MBL\textsuperscript{33} in these patients. The same is true for a series of other conditions such as bruxism,\textsuperscript{34} diabetes,\textsuperscript{35} and the intake of antidepressants\textsuperscript{36} or of medicaments to reduce the gastric acid production.\textsuperscript{37} Detailed information about these conditions and habits among the patients was, however, not provided for every patient by the publications. Another point to consider is that patients with secondary SS showed a higher implant failure rate than patients with primary SS. Even though the difference was not statistically significant, there might be some clinical relevance and significance. The usual intake of corticosteroids for the management of underlying rheumatic diseases in the patients with secondary SS could be partly associated with impaired osseointegration. Corticosteroids induce apoptosis of osteoblasts,\textsuperscript{38} reducing the number of pre-osteoblasts,\textsuperscript{39} and promoting differentiation of bone marrow stromal cells to adipocyte lineage cells.\textsuperscript{40} Moreover, corticosteroids increase the life span of osteoclasts\textsuperscript{41} and suppress bone formation via the osteoclast.\textsuperscript{42} Besides corticosteroids, methotrexate\textsuperscript{43} and biological-targeted therapies, including TNF-α inhibitors and rituximab,\textsuperscript{44} have been used in patients with primary SS-associated inflammatory arthritis. Methotrexate has been shown to be a potent inhibitor of osteoblast's proliferation and mitochondrial metabolism \textit{in vitro},\textsuperscript{45} and to have the potential to interfere with the osseointegration process.\textsuperscript{46} Concerning biological
agents, these have been found to have effects on human chondrocytes and osteocytes in vitro,\textsuperscript{47} and to present a significant suppression in bone turnover.\textsuperscript{48} These drugs can have some impact on wound healing and osseointegration, not only the underlying SS itself. The higher MBL in primary SS patients in comparison to secondary SS patients can be either a true finding, being related to the negative effects of the abovementioned drugs in primary SS patients, or be related to a shorter radiological follow-up for the secondary SS patients and a much smaller sample size at the last follow-up. More balanced groups are necessary in order to confirm this difference.

All in all, the findings from the present study suggest that SS itself does not impair the biology of osseointegration. It may, however, result in a higher MBL than in non SS patients, which may require an increased number of recall visits and shortened professional hygiene intervals.

The limitations of the present study include (1) the presence of confounding factors that may have affected and influenced the outcomes,\textsuperscript{49} (2) the retrospective design of the studies included in the systematic review, as well as the present case series of 19 patients, (3), the lack standardized timing for evaluating the radiographs and low percentage of MBL measurements due to the retrospective nature of the case series, and (4) the fact that most studies reported a small number of patients followed up for a limited period of time.

**CONCLUSIONS**

Dental implants should be considered by dentists as a viable treatment option in patients with SS, as the failure rate is fairly low: 4.2\% over a mean of 73.1±59.8 months of follow-up. The SS patients may, however, present a higher MBL around implants than in the general population.
ACKNOWLEDGEMENTS

We would like to thank Dr. Alan B. Carr, Dr. Johanna Callhoff, Dr. Katinka Albrech, and Dr. Anke Korfage for providing us some missing information about their studies.

Trial registration at the U.S. National Institutes of Health (clinicaltrials.gov): NCT02369562.
